## HIGHLIGHTS

• Negative contribution of chemistry to  $O_3$  was significantly weakened due to COVID-19 lockdown.

•  $1<sup>st</sup>$  and  $2<sup>nd</sup>$ -order O<sub>3</sub> sensitivities to NO<sub>x</sub> were negative and positive, respectively.

•  $2<sup>nd</sup>$ -order O<sub>3</sub>-NO<sub>x</sub> sensitivity increased 3 times due to COVID-19 lockdown. • Higher rate of  $O_3$  increase due to  $NO_x$  reductions during COVID-19 lockdown.

ARTICLE INFO

*Keywords:*  Ozone CMAQ HDDM-3D Sensitivity analysis COVID-19 Yangtze River Delta ABSTRACT

Elevated ozone  $(O_3)$  concentration during the COVID-19 lockdown is a matter of great concern, but the changes of its sensitivities to key precursors remains unclear. This study utilized the Community Multiscale Air Quality (CMAQ) model coupled with the Higher-order Decoupled Direct Method in Three Dimensions (HDDM-3D) and the process analysis (PA) modules to reveal in detail the changes in  $O_3$ -precursors sensitivities and the contribution of major chemical and physical processes to  $O<sub>3</sub>$  formation/loss during the month-long COVID-19 lockdown in early 2020 over the Yangtze River Delta (YRD) region of China. The results indicate that the contributions (absolute value) of gas-phase chemistry to  $O_3$  and  $O_x$  (i.e.,  $O_3+NO_2$ ) were reduced by 35–50% and 8–24%, respectively, under lockdown-specific (LCD) scenario compared with the business-as-usual (BAU) scenario in the highly urbanized areas of eastern and central YRD. Under the BAU (LCD) scenario, the first-order and second-order O<sub>3</sub>-NO<sub>x</sub> sensitivities averaged about  $-25$  ( $-36$ ) µg/m<sup>3</sup> and about 8 (28) µg/m<sup>3</sup>, respectively. These  $1<sup>st</sup>$ - and  $2<sup>nd</sup>$ -order sensitivities of O<sub>3</sub> to NO<sub>x</sub> were both intensified due to COVID-19 lockdown, which potentially contributed to  $O_3$  increases of between 5 and 10  $\mu g/m^3$ . In other words, the concentration of  $O_3$  and its rate of increase were both amplified due to COVID-19 lockdown. Overall, this study highlighted a significant wintertime "NO<sub>x</sub> reduction disbenefit" phenomenon over YRD because of both strong 1<sup>st</sup>-order (negative) and 2<sup>nd</sup>-order (positive)  $O_3$  sensitivities to NO<sub>x</sub> emissions, which were further reinforced due to COVID-19 lockdown.

### **1. Introduction**

The emergence of the COVID-19 outbreaks since late 2019 created an extreme global disruption of human life. In response, the government of the People's Republic of China (PRC) quickly activated national emergency containment protocols to reduce the intensity of the epidemic, which included stringent "stay-at-home" policy known as the "COVID-19 lockdown" [\(Tian et al., 2020\)](#page-12-0). This necessitated the closure, halting or lessening of industrial operations, transportation services, construction works, restaurant and catering facilities, educational institutions, among others. This massive embargo led to substantial reduction of major air pollutant emissions ([Muhammad et al., 2020](#page-12-0)) and an overall improvement of air quality in China [\(Liu et al., 2021](#page-12-0); [Pei et al., 2020](#page-12-0)). However, during the same period several Chinese cities experienced significant increases in the concentrations of ground-level ozone  $(O_3)$ ([Lian et al., 2020](#page-12-0); [Pei et al., 2020](#page-12-0); [Wang et al., 2020b](#page-12-0); [Zhao et al., 2020](#page-13-0)). This peculiar  $O_3$  increases during the lockdown period were also re-ported in some cities in Europe [\(Collivignarelli et al., 2020](#page-12-0); Ordóñez [et al., 2020;](#page-12-0) [Sicard et al., 2020\)](#page-12-0), South America ([Cazorla et al., 2021](#page-12-0); [Siciliano et al., 2020\)](#page-12-0), as well as in India ([Shehzad et al., 2020\)](#page-12-0).

Understandably,  $O_3$  formation is usually a nonlinear chemical process strongly dependent on the concentrations of nitrogen oxides  $(NO<sub>x</sub>)$  $= NO<sub>2</sub>+NO)$ , volatile organic compounds (VOCs) as well as the intensity of sunlight ([Atkinson, 2000](#page-12-0)). Once these precursors are emitted into the troposphere, instant  $O_3$  formation is initiated via a rapid and coupled sequence of radical cycles involving  $NO<sub>x</sub>$  and  $RO<sub>x</sub>$  (i.e., organic peroxy (RO2), hydroperoxy (HO2) and hydroxyl (OH)) [\(Li et al., 2018](#page-12-0); [Wang](#page-12-0)  [et al., 2017\)](#page-12-0). This mechanism, although more complex in real atmosphere, forms the core of the photochemical formation of tropospheric  $O_3$ . In principle, any changes that can influence the sources of  $NO_x$  and VOCs emissions would significantly impact the  $O<sub>3</sub>$ -precursors relationship and ultimately result in an unexpected  $O_3$  formation outcome (Tang [et al., 2021](#page-12-0)), which was evident during the COVID-19 lockdown period ([Liu et al., 2021\)](#page-12-0). Therefore, it is prudent to gain deeper insights into the underlying response of  $O_3$  following the drastic reductions of  $NO<sub>x</sub>$  and VOC emission during the lockdown period. This will significantly benefit ongoing and prospective  $O_3$  control strategies.

Over the Yangtze River Delta (YRD) region which is one of the world's largest urban agglomerations in the world, a number of recent studies have made significant attempts to understand the dramatic increase in  $O_3$  levels during COVID-19 lockdown. Wang et al. (2021) linked these  $O_3$  increases to an enhancement of the atmospheric oxidation capacity (AOC), similar to the findings by [Zhu et al. \(2021\)](#page-13-0). In sharp contrast, another study by [Wang et al. \(2022a\)](#page-12-0) reported a widespread reduction of AOC over the YRD region during the same lockdown period, and noted a significant decline in the chemical consumption of O3 by nitric oxide (NO) to have had an overwhelming effect that resulted in net  $O_3$  increase. In addition, some studies reported a dramatic shift in O3-precursors sensitivity regimes over YRD during the lockdown period. For instance, using photochemical indicator ratios (PIRs) [Zhu et al.](#page-13-0)  [\(2021\)](#page-13-0) and [Wang et al. \(2021\)](#page-12-0) applied the ratios of formaldehyde (HCHO) to  $NO<sub>2</sub>$  columns, and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) to nitric acid (HNO3) production rates, respectively, and found a conspicuous change of  $O_3$  chemical regimes from VOC-limited regimes to  $NO<sub>x</sub>$ -limited during the lockdown period. On the other hand, using an observation-based model (OBM) [Zhang et al. \(2022\)](#page-12-0) also noted that  $O_3$  formation conditions switched from VOC-limited to the border of a  $NO<sub>x</sub>$ - and VOC-limited regime. However, it should be noted that PIRs are entirely based on  $O_3$  formation (and not  $O_3$  removal) and therefore do not account for photochemical aging.

Actually, accurate diagnosis of these regimes (especially for  $NO<sub>x</sub>$ titration) is usually quite challenging (Sillman and West,  $2009$ ). NO<sub>x</sub>-titration is typically dominant in areas (and time) with intense sources of directly emitted  $NO<sub>x</sub>$ , and therefore  $O<sub>3</sub>$  concentrations are consumed by the reaction  $O_3 + NO \rightarrow NO_2$  rather than photochemical production ([Sill](#page-12-0)[man and He, 2002](#page-12-0)). For OBMs, since it does not consider the effect of atmospheric transport, which has a great influence on the concentration change of ozone at a given location, this method is also insufficient in diagnosing the sensitivity of ozone to precursors. Moreover, the application of OBMs is very limited in space because it is based on observational data.

Three-dimensional chemical transport models (CTMs) have unique advantages in studying the sensitivity of ozone to precursors because they include emissions, chemical processes, atmospheric transport, and deposition. Over the past decade, state-of-the-art CTMs have been sufficiently equipped with tools that can adequately characterize complex atmospheric relationships such as that of  $O_3$  and its precursors (Liu et al., [2020; Sharma et al., 2017](#page-12-0)). For instance, the Community Multiscale Air Quality (CMAQ) model ([Byun and Schere, 2006](#page-12-0)) in the recent past was instrumented with a powerful higher-order sensitivity analysis tool (i.e., the HDDM-3D, Higher-order Decoupled Direct Method in Three Dimensions) [\(Hakami et al., 2003](#page-12-0)), which can efficiently and simultaneously compute  $O_3$ -NO<sub>x</sub>-VOCs sensitivities ([Cohan et al., 2005\)](#page-12-0) while accounting for nonlinear interactions [\(Arter and Arunachalam, 2021](#page-12-0)). Moreover, sensitivity outputs from HDDM-3D have been utilized to identify the sources contributing to  $O_3$  formation over east Asia (Itahashi [et al., 2015\)](#page-12-0); for innovative construction of  $O_3$  isopleths to support abatement strategies in China ([Shen et al., 2021a](#page-12-0)); as well as to investigate  $O_3$ -NO<sub>x</sub>-VOCs sensitivities and characterize  $O_3$  chemical regimes during a severe pollution episode in YRD ([Wang et al., 2022b](#page-12-0)). Although the traditional CTM-based brute force method (BFM) can achieve relatively similar results, the HDDM method has been found to be more flexible and efficient in implementation particularly for several sensitivity parameters notwithstanding the computing resources required ([Huang et al., 2017; Shen et al., 2021b; Zhang et al., 2012\)](#page-12-0). Moreover, HDDM-3D not only can quantitatively identify the sensitivity of  $O_3$  to precursor emissions, but also can quantify the response of this sensitivity to changes in precursor emissions based on the second-order sensitivity coefficients, which are of great importance for ozone pollution mitigation decision-making.

In this work, the CMAQ-HDDM-3D method was adopted to comprehensively reveal the changes of the first- and second-order sensitivities of  $O_3$  to its precursors in the YRD region during the COVID-19 lockdown. This way, we can explore in detail the responsiveness of  $O_3$  to the substantial changes in anthropogenic emissions of its precursors, and eventually uncover important insights into the underlying cause of elevated O<sub>3</sub> levels observed during the lockdown period. Although the overall COVID-19 lockdown policy was effected from 24<sup>th</sup> January to 31<sup>st</sup> March over the YRD region, this study focused on the period from 24<sup>th</sup> January to around February 24<sup>th</sup>, 2020 (i.e., when strict "Level-I" measures were effected, hereafter referred to as LD-I) [\(Li et al., 2020\)](#page-12-0). In addition, we also utilized the process analysis (PA) tool embedded in CMAQ to examine the changes in contributions of physical and chemical processes to ozone during COVID-19 lock down period.

## **2. Methodology**

## *2.1. Model configuration*

A set of three integrated modelling systems consisting of a CTM, regional meteorological model and an emission processor, were configured to adequately cover both the pre-lockdown (PLD) and LD-I study period between 6th January to February 24, 2020. As shown in [Fig. 1](#page-2-0), Lambert Conformal map projection and three domains with horizontal resolutions of 36 km, 12 km, and 4 km, respectively, were used in this study. These domains were vertically divided into 14 layers. The innermost/target domain covers the entire YRD region, which includes the three provinces of Zhejiang, Jiangsu and Anhui and the municipality of Shanghai. There are 41 prefecture cities in the YRD region and Hangzhou, Nanjing, and Hefei are the capital cities of Zhejiang, Jiangsu, and Anhui provinces, respectively. In this study, we focus on at least one typical urban site in Shanghai (Jing'an: JA), Hangzhou

<span id="page-2-0"></span>

**Fig. 1.** Modeling domains and locations of the national observational sites. The four rural sites are Dianshan Lake (DSL), Qiandao Lake (QDL), Dongpu Reservoir (DPR) and Shangfang Mountain (SFM).

(Wolong bridge: WB), Nanjing (Caochangmen: CM) and Hefei (Mingzhu square: MS), as well as four other typical rural/suburban sites of YRD region that includes Dianshan Lake (DSL), Qiandao Lake (QDL), Dongpu Reservoir (DPR) and Shangfang Mountain (SFM) (Fig. 1).

The CMAQ model version 5.3.3 was used to simulate air quality. PA and HDDM-3D tools embedded in the CMAQ model provided the outputs to analyse processes and  $O_3$ -NO<sub>x</sub>-VOCs sensitivities, respectively. The Weather Research and Forecasting (WRF) model version 4.0 ([Ska](#page-12-0)[marock et al., 2019](#page-12-0)) was used to generate the meteorological inputs required to drive the CMAQ model. Additionally, the Sparse Matrix Operator Kernel Emissions model (SMOKE, [https://www.cmascenter.](https://www.cmascenter.org/smoke)  [org/smoke\)](https://www.cmascenter.org/smoke) was used to process the anthropogenic emissions files into a format suitable for the CMAQ model. The air quality simulation for the areas outside YRD were based on the multi-resolution (anthropogenic) emission inventory for China (MEIC,<http://www.meicmodel.org/>). The emission inventory of the YRD region used in this work is the same as what was utilized in a previous study [\(Li et al., 2020\)](#page-12-0). The Model of Emissions of Gases and Aerosols from Nature (MEGAN) ([Guenther et al.,](#page-12-0)  [2012\)](#page-12-0) version 3.0 (<http://bai.ess.uci.edu/megan>) was used to generate the biogenic emission inventory. The domain setup and configurations used in this work are the same that were utilized in a recent study (Wang [et al., 2022b](#page-12-0)).

## *2.2. Simulation scenarios*

In this study, CMAQ model was configured to simulate two distinct scenarios. The first simulation scenario (hereafter referred to as the BAU scenario) was run with "normal" or "business-as-usual" anthropogenic emissions during the COVID-19 lockdown period (from 24<sup>th</sup> January to around February 24th, 2020, the LD-I period mentioned above). The other simulation scenario (hereafter referred to as the LCD scenario) was run with an anthropogenic emissions inventory after changes in emissions caused by the lockdown during the COVID-19 lockdown period (LD-I period mentioned above). It is also noteworthy that there were great changes of the emissions of a number of pollutants during the LD-I lockdown period compared with the normal scenario (BAU). These various changes of emissions associated with the changes of the activity data in various sectors during the lockdown period (LCD scenario) was estimated by [Li et al. \(2020\),](#page-12-0) as shown in Table S1, which reflects the perturbations of anthropogenic emissions for the LCD scenario. On average, the total change in the emissions of  $SO_2$ ,  $NO_x$ ,  $CO$ ,  $VOCs$ ,  $PM_{10}$ and PM<sub>2.5</sub> during LD-I lockdown period were  $-26\%$ ,  $-47\%$ ,  $-39\%$ , − 57%, − 61%, and − 46%, respectively. Moreover, VOCs emissions from

sources of household solvent usage and hospital solvent usage increased by 30% in their estimation. More details can be found in a previous study by [Li et al. \(2020\).](#page-12-0)

## *2.3. Process analysis of ozone formation*

Being cognizant of the various complex chemical and physical processes interactions involved in  $O_3$  formation, we activated the PA functionality within CMAQ in all our simulations to account for (and distinguish) the contributions of emissions, chemistry, transport and deposition processes while computing pollutant concentrations ([Gon](#page-12-0)[çalves et al., 2009\)](#page-12-0). Essentially, we analyzed the hourly integrated process rate (IPR) contributions of gas-phase chemistry (CHEM), cloud and aqueous processes (CLDS), dry deposition (DDEP), vertical advection (ZADV), vertical diffusion (VDIF), horizontal advection (HADV), and horizontal diffusion (HDIF). Several studies have previously utilized and demonstrated the effectiveness of PA in explaining  $O<sub>3</sub>$  formation over YRD [\(Li et al., 2012; Lu et al., 2020; Ni et al., 2020; Shu et al., 2016](#page-12-0); [Wang et al., 2022a](#page-12-0)).

## *2.4. O3-precursor sensitivity analysis based on HDDM-3D*

Sensitivity analysis provides an estimate of the impacts caused by changes in emissions (or any other parameter) on ambient concentrations of atmospheric pollutants, and is a widely used approach to support air quality decisions and to inform effective emission control strategies ([Clappier et al., 2017;](#page-12-0) [Cohan and Napelenok, 2011\)](#page-12-0). In this study, a detailed  $O_3$ -NO<sub>x</sub>-VOCs sensitivity analysis is performed with CMAQ-HDDM-3D tool. The sensitivity coefficients of  $O_3$  to  $NO_x$  and VOC emissions were calculated as follows:

$$
S^{(1)} = E_0 \frac{\partial C}{\partial e} = E_0 \frac{\partial C}{\partial [(1 + \Delta \varepsilon) E_0]} = \frac{\partial C}{\partial \varepsilon}
$$
(1)

$$
S^{(2)} = E_0 \frac{\partial}{\partial e} \left( E_0 \frac{\partial C}{\partial e} \right) = \frac{\partial^2 C}{\partial e^2}
$$
 (2)

where  $S^{(1)}$  and  $S^{(2)}$  are the first- and second-order sensitivity coefficients, respectively.  $\varepsilon$  is a scaling variable of the emission of NO<sub>x</sub> or VOCs, hence both the sensitivity coefficients and concentration have same units. Therefore, if for instance  $S^{(1)}$  is equal to  $+\alpha$  ppb ( $-\alpha$  ppb), it implies that with a  $+10\%$  perturbation in NO<sub>x</sub> (or VOC) emissions, the concentration of O<sub>3</sub> would change by +  $0.1\alpha$  ppb ( $-0.1\alpha$  ppb). Similarly, if <span id="page-3-0"></span>for instance *S*<sup>(2)</sup> is equal to +β ppb (-β ppb), it implies that with a +10% perturbation in NO<sub>x</sub> (or VOC) emissions, instance  $S^{(1)}$  would change by  $+0.1\beta$  ppb ( $-0.1\beta$  ppb).

Here, to quantify the impacts of the lockdown emission reductions on  $O_3$  we utilized both the first- and second-order  $O_3$  sensitivities with respect to  $NO<sub>x</sub>$  and VOCs based on the Taylor series expansions (Eq. (3)):

$$
C_{P(e=E_0+\Delta\varepsilon,E_0)} \approx C_{0(e=E_0)} + \Delta\varepsilon.S^{(1)} + \frac{(\Delta\varepsilon)^2}{2}.S^{(2)}
$$
\n(3)

 $C_p$  is the pollutant concentration (i.e.,  $O_3$  in this study) after a fractional perturbation ( $\Delta \varepsilon$ ) in the emissions (*e*) of either NO<sub>x</sub> or VOCs. The fractional perturbation ( $\Delta \varepsilon$ ) is the change of scaling variable of the emission of  $NO<sub>x</sub>$  or VOCs.  $E<sub>0</sub>$  and  $C<sub>0</sub>$  both represent the normal or business-as-usual emissions and concentrations, respectively. With this, we rapidly determined the extent of  $O_3$  increases due to the emission reductions of VOCs and/or  $NO<sub>x</sub>$  at each grid cell over the YRD region, which facilitated a better understanding of the impact of emission controls on  $O_3$  concentration over the YRD region. A detailed description of the structure, equations of sensitivity of  $O_3$  to its precursors can be found in previous study by ([Wang et al., 2022b](#page-12-0)).

#### *2.5. Model performance assessment*

This study utilized the same WRF input files used by [Li et al. \(2020\)](#page-12-0), and the meteorological predictions covering the study period for this work have been well evaluated therein. In brief, the WRF predictions were found to be generally consistent with ground measurements, although there was a slight disagreement (negative bias) in the prediction of relative humidity. For the CMAQ model performance, the hourly simulated  $O_3$  and  $NO_2$  concentrations were compared with ground-based observations between 6 January to February 24, 2020, which adequately covers the period before (PLD) and during the lockdown (LD-I) over the YRD region. The ground measurements during this period were obtained from all the monitoring stations in all the 41 major cities across the YRD region, while the model simulations are average values at the grid cells corresponding to each monitoring station. We pay particular emphasis to the model performance results in the four key representative (capital) cities of Shanghai, Hangzhou, Nanjing and Hefei ([Fig. 1](#page-2-0)). The results of the simulation-observation comparisons and statistical evaluation for both  $O_3$  and  $NO_2$  during the study period are summarized in the Supplementary Information (SI). Even with the slight under predictions, the CMAQ model captured relatively well the overall trend of  $O_3$  and  $NO_2$  during the study period, including the conspicuous increases that were observed during the COVID-19 lockdown period. Furthermore, as shown in Text S2 in the supplementary information our model performance results were largely comparable with previous studies ([Liu et al., 2021;](#page-12-0) [Wang et al., 2021](#page-12-0), [2022a](#page-12-0)). Therefore, the CMAQ outputs for this study can therefore be utilized objectively for a detailed analysis of  $O_3$ -precursors relationship and to understand the  $O_3$ increases observed during the lockdown period over the YRD region.

## *2.6. Data sources*

To understand the spatial and temporal distribution of  $O<sub>3</sub>$  during the study period, we used ground measurements collected from all the 223 national monitoring sites in the 41 major cities within YRD [\(Fig. 1](#page-2-0)). These observations are archived at a repository maintained by the Ministry of Ecology and Environment of the People's Republic of China (<http://datacenter.mep.gov.cn>). Additionally, owing to the general lack of observations for VOCs over the YRD region, we obtained continuous measurements from 8 January to March 31, 2020 collected at a typical urban location in Changzhou city in the central of YRD, which adequately cover the period considered in this study. The methodology and processes involved in VOC data collection have been well covered in detail elsewhere ([Zhang et al., 2022](#page-12-0)). For meteorological observations,

we utilized hourly data from the weather monitoring sites in the 41 cities over YRD provided by the China Meteorological Administration (CMA: [https://data.cma.cn/\)](https://data.cma.cn/).

## **3. Results and discussion**

As mentioned previously, a number of studies illustrated generally consistent changes in air quality over the YRD with regards to the lockdown restrictions [\(Huang et al., 2020](#page-12-0); [Li et al., 2020;](#page-12-0) [Lian et al.,](#page-12-0)  [2020;](#page-12-0) [Miyazaki et al., 2020](#page-12-0); [Pei et al., 2020;](#page-12-0) [Shi and Brasseur, 2020](#page-12-0); [Wang et al., 2020b\)](#page-12-0). Li et al.  $(2020)$  found that apart from  $O_3$ , the average concentrations of  $PM_{2.5}$ ,  $PM_{10}$ , CO, NO<sub>2</sub> and SO<sub>2</sub> before (during) the lockdown reduced in 2020 by 12.3% (31.8%), 19.6% (33.7%), 7.8% (20%), 18.5% (45.1%) and 29.3% (20.4%), respectively, compared to similar period in 2019. The most puzzling change (and which is significant to our current study) relates to the significant increase of  $O_3$ , while its main precursors (e.g., NO<sub>x</sub>) reduced substantially [\(Li et al., 2020](#page-12-0); Liu [et al., 2021;](#page-12-0) [Zhao et al., 2020](#page-13-0); [Zhu et al., 2021](#page-13-0)). Text S1, Fig. S1 and Table S2 in the SI describes an overview of the evolution pattern and changes of  $O_3$ ,  $NO_x$  and VOCs based on ground observations during PLD and LD-I periods juxtaposed with similar period in the previous three years (2017–2019 average). Here, we undertake a deeper exploration of these  $O_3$  concentration changes before and during the lockdown period over the YRD region.

## *3.1. O3 increases over YRD during COVID-19 lockdown*

[Fig. 2](#page-4-0) shows the comparison of the daytime (9:00–16:00 local time, LT) concentrations of  $O_3$  observations alongside the simulated concentrations for both the "BAU" and "LCD" scenarios averaged for all the national control monitoring stations in each of the key representative cities of Shanghai, Nanjing, Hangzhou and Hefei. We noted obvious increases of daytime  $O_3$  during LD-I period relative to PLD ([Fig. 2](#page-4-0)a), and the lowest and highest relative changes of observed ("BAU", "LCD") were about 43.9 (14.6, 67.1)% in Shanghai and 82.5 (49.1, 83.3)% in Hefei, respectively ([Fig. 2b](#page-4-0)). Furthermore, as a result of the emission reductions during LD-I, highest daytime  $O<sub>3</sub>$  concentration increases occurred in Shanghai (24.2 μg/m<sup>3</sup>), followed by Hangzhou (17.6 μg/ m<sup>3</sup>), Nanjing (16.6 μg/m<sup>3</sup>) and Hefei (12 μg/m<sup>3</sup>) ([Fig. 2c](#page-4-0)). As expected, because Shanghai is a much larger city with intense emissions of  $O<sub>3</sub>$ precursors (especially  $NO<sub>x</sub>$ ), the impact of the COVID-19 lockdown controls on  $O_3$  is certainly relatively higher than in the other key cities. This certainly shows that the control measures implemented during LD-I had significantly higher impact on  $O<sub>3</sub>$ , and our results are generally consistent with other related studies that found closely similar  $O_3$  increases during COVID-19 lockdown over the YRD region ([Liu et al.,](#page-12-0)  [2020, 2021](#page-12-0); [Wang et al., 2022a\)](#page-12-0).

## *3.2. Process analysis of ozone formation during the COVID-19 lockdown*

Different atmospheric processes played an important role in  $O_3$  formation during the lockdown period. This includes the net effect of chemistry, transport, and deposition processes. We noted that for both the BAU and LCD scenarios gas-phase chemistry (CHEM), vertical transport (VERT=VDIF  $+$  ZADV), dry deposition (DDEP), and to some extent horizontal transport (HORT=HADV + HDIF) were generally the dominant processes that can explain the spatiotemporal evolution pattern (including the removal or increases) of  $O_3$  during the lockdown period over the YRD region. The aqueous and clouds chemistry contribution (not shown) had nearly negligible contribution to  $O<sub>3</sub>$  during the study period and was not included in our analysis. As shown in [Fig. 3](#page-5-0), CHEM and DDEP were the major process that consumed  $O<sub>3</sub>$  (indicated by negative magnitudes) especially in the urbanized areas of YRD, whereas VERT (dominated by positive magnitudes of VDIF) largely contributed in compensating and balancing off the  $O_3$  losses.

Moreover, other than the widely varied contribution of HORT

<span id="page-4-0"></span>

**Fig. 2.** (a) Daily variation of daytime averaged  $(9:00-16:00$  LT)  $O_3$  observations compared with the modeled "BAU" and "LCD" scenarios during PLD and LD-I in 2020 averaged at all the national control sites in Shanghai (SH), Nanjing (NJ), Hangzhou (HZ) and Hefei (HF). **(b)** Changes in observed and modeled daytime  $O_3$  concentration during LD-I compared with PLD, and **(c)** averaged relative changes (LCD-BAU) during LD-I show the impact of COVID 19 lockdown on O3. The red dashed line defines the pre-lockdown period (PLD) between  $6<sup>th</sup>$  to  $23<sup>rd</sup>$  January and lockdown Level I control period (LD-I) 24<sup>th</sup> January to 24th February 2020.

(dominated by HADV) to  $O_3$  in different areas of YRD (see Fig. S4a in the SI), CHEM and VDIF exhibited higher magnitudes under the BAU scenario ([Fig. 3](#page-5-0)a), which significantly reduced under the LCD scenario ([Fig. 3](#page-5-0)b). Save for the slight increase in DDEP, the most notable IPR difference relates to the significant reduction of CHEM contribution that occurred primarily in the eastern and centrals areas of YRD where  $O<sub>3</sub>$ concentration increases were highest [\(Fig. 3c](#page-5-0)). This includes the most urbanized cities of Ningbo, Hangzhou, Shanghai, Suzhou and Nanjing among others. Because these cities are inherently within the most developed core region of YRD where intense emission of  $O<sub>3</sub>$ -precursors from anthropogenic sources is usually prevalent ([An et al., 2021](#page-12-0)), it then means that the lockdown restrictions directly lowered the capacity of chemical consumption of  $O_3$  via NO-titration due to the substantial reduction of  $NO<sub>x</sub>$  emissions during LD-I. These findings are generally consistent with previous studies [\(Li et al., 2020](#page-12-0); [Wang et al., 2020a](#page-12-0), 2022a). However, although there was an increase in DDEP during LD-I, the enhancement was too little to balance off the much higher reduction in CHEM ([Fig. 3](#page-5-0)c). Furthermore, the daytime CHEM contribution to odd oxygen (CHEM-O<sub>x</sub>) hardly exceeded 5  $\mu$ g/m<sup>3</sup> for both simulation scenarios, but instead it exhibited a general reduction under the LCD scenario even in areas that exhibited higher  $O_3$  increases as shown in Fig. S4b in the SI.

From a temporal perspective [\(Fig. 4](#page-6-0) and Fig. S5), the simulated  $O_3$ concentrations exhibited a typical diurnal pattern during LD-I: low levels in the early morning hours, followed by a steady increase during mid-morning, before peaking in the afternoon, and thereafter declining gradually to low levels in the evening. As shown in [Fig. 4](#page-6-0), the lowest  $O_3$ concentrations and the conspicuously pronounced negative CHEM contribution occurred between 6:00–8:00 LT and from around 18:00–19:00 LT, which is mainly the result of the combined effects of diurnal changes in meteorological conditions (such as changes in the height of the boundary layer, changes in radiation intensity) and diurnal changes in emissions.

Between 9:00-16:00 LT CHEM contribution to  $O_3$  weakened, whereas CHEM- $O_x$  as well as  $O_3$  concentrations increased correspond-ingly [\(Fig. 4\)](#page-6-0). This pattern between CHEM- $O_x$  and  $O_3$  concentration was also similar at the rural sites (Fig. S5). However, compared to the urban locations, the IPR magnitudes were significantly lower and relatively the same between the BAU and LCD scenarios at the rural sites. Moreover, other than the rural SFM site, dry deposition was the main sink for  $O_3$  in the other typical rural sites in addition to the dismal contribution of CHEM. Logically, there is an overall lower emission of  $NO<sub>x</sub>$  in rural locations than in urban areas, hence the obvious lower impact of  $O_3$ consumption through NO-titration.

The vertical profile of IPR outputs is shown in [Fig. 5.](#page-6-0) We note that within the atmospheric boundary layer (ABL: i.e. modeling layer 1–8 in this study), the variation of the magnitudes of the main processes contributing to  $O_3$  formation and removal were higher at the surface than in the upper layers. Gas-phase chemistry continued to significantly consume  $O_3$  from the surface to about layer 5 ( $\sim$ 350 m above ground level), while both vertical and horizontal transport processes not only balanced off the  $O_3$  loss through CHEM but led to additional  $O_3$  especially over most of the urban atmosphere. Notably, as height above the ground surface increased in the urban areas, and at higher altitude the contribution of CHEM and VERT processes diminished and became increasingly positive and negative, respectively [\(Fig. 5\)](#page-6-0). For instance, at the urban sites in Shanghai (JA), Hangzhou (WB), and Hefei (MS) cities, the contribution of chemistry to ozone transitioned to being positive (albeit with a small magnitudes) beyond  $\sim$  500 m,  $\sim$  160 m and  $\sim$  240 m above the ground level respectively ([Fig. 5](#page-6-0)). At the suburban DSL (in Shanghai) and DPR (in Hefei) the negative chemical contribution was confined within  $\sim$ 160 m and  $\sim$ 90 m, respectively, whereas at the rural QDL site, chemistry contributed positively from the surface to more 2 km above the surface (Fig. S6). This means that at upper layers towards the top of the ABL, gas-phase chemistry (though dismal) contributed positively to  $O_3$  production, and the  $O_3$  formed was then transported downwards via VDIF. It is understandable that solar radiation is relatively higher at such high altitudes, which create more favourable conditions for photochemical reactions, and which could yield more O<sub>3</sub> than at the surface. At the rural sites, the first layer revealed the only significant magnitudes of IPR outputs (Fig. S6), which were still much lower than in the urban locations. Overall, whether at the urban or rural sites, the magnitudes of most dominant processes that contributed to  $O_3$ during LD-I were much higher at (or near) the surface for both scenarios,

<span id="page-5-0"></span>

Fig. 3. Spatial distribution of simulated daytime (9:00-16:00 local time) average ground-level O<sub>3</sub> concentration (CONC) and their corresponding contributions from gas-phase chemistry (CHEM), vertical diffusion (VDIF) and dry deposition (DDEP) over the YRD region during LD-I period. (**a**) Represent BAU scenario, (**b**) is for LCD scenario and (c) is the difference between LCD and BAU. (LD-I is the COVID-19 lockdown period between 24<sup>th</sup> Jan.-24<sup>th</sup> Feb 2020).

which could explain the much wider gap and lower levels of  $O_3$  concentration at the surface than at higher altitudes. This also indicates that the emission reduction measures during the lockdown period had a significant impact on the chemistry and ultimate formation of  $O<sub>3</sub>$  at the surface.

For a closer look at Figs. 3, [Figs. 4](#page-6-0) and [5](#page-6-0), the BAU scenario exhibited larger IPR magnitudes and lower  $O<sub>3</sub>$  levels, while the LCD scenario showed significantly reduced IPR magnitudes and substantial increase in  $O_3$  levels. To understand the scale of these changes, we computed the differences between the two scenarios at both the urban and rural sites as shown in [Table 1](#page-7-0). Among the urban and rural/suburban sites the highest changes in O<sub>3</sub> (CHEM, VERT) of about 22.75 ( $-20.2, -17.3$ ) µg/ m<sup>3</sup> and 13.96 (−12.4, −10.9)  $\mu$ g/m<sup>3</sup> occurred at Shanghai-JA (among

the urban sites) and SFM (among the rural sites), respectively. On the other hand, lowest changes of about 12.10 ( $-13.5$ ,  $-10.7$ )  $\mu$ g/m<sup>3</sup> and 5.41 ( $-0.67, -0.81$ ) μg/m<sup>3</sup> were prevalent at the urban Hefei-MS and at the rural QDL sites, respectively. These relatively low changes generally reflect the lower intensity of O<sub>3</sub>-precursor emissions, which is synonymous of the obvious lower contribution of the main IPR variables to the O3 levels at these sites.

As mentioned previously, the combined decrease of VERT and the enhancement of DDEP still didn't balance off the higher decline of CHEM contribution during LD-I. For instance, in the urban sites of Shanghai, Hangzhou, Nanjing and Hefei the change in CHEM (VERT, DDEP) was about  $-20.2$  ( $-17.3$ , 0.03)  $\mu$ g/m<sup>3</sup>, -16.8 ( $-13.4$ , 1.37)  $\mu$ g/ m<sup>3</sup>, -12.2 (-9.71, 1.67)  $\mu$ g/m<sup>3</sup> and -13.5 (-10.7, 1.31)  $\mu$ g/m<sup>3</sup>,

<span id="page-6-0"></span>

Fig. 4. Diurnal variations of  $O<sub>3</sub>$  concentrations and the main atmospheric processes contributions at the surface layer (0–40 m) for the BAU and LCD scenario during LD-I at typical urban locations in Shanghai, Hangzhou, Nanjing and Hefei. (CHEM: gas-phase chemistry; DDEP: dry deposition; VERT: vertical transport, i.e. the net effect of ZADV and VDIF; HORT: horizontal transport, i.e. the net effect of HADV and HDIF; CHEM-O<sub>x</sub>: gas-phase chemistry contribution to  $O_x$ ; CONC: average  $O_3$  concentration). LD-I is the COVID-19 lockdown period between 24<sup>th</sup> January-24<sup>th</sup> February 2020.

**Fig. 5.** Vertical profile of simulated daytime average (09:00–16:00 LT)  $O_3$  concentration and the main atmospheric processes contributions under the BAU and LCD scenarios during LD-I for the model layers 1–8 at typical urban sites in Shanghai, Hangzhou, Nanjing and Hefei. (CHEM: gas-phase chemistry; DDEP: dry deposition; VERT: vertical transport, i.e. the net effect of ZADV and VDIF; HORT: horizontal transport, i.e. the net effect of HADV and HDIF; CHEM-O<sub>x</sub>: gasphase chemistry contribution to  $O_x$ ; CONC: average O3 concentration). The inset figures show the vertical profile of CHEM contribution. The approximate height of each model layer is as defined in Table S9. LD-I is the COVID-19 lockdown period in YRD region between 24<sup>th</sup> January-24<sup>th</sup> February 2020.

respectively ([Table 1](#page-7-0)). This indicates that the substantial changes in gasphase chemistry (unlike transport and deposition processes) could sufficiently explain the possible impact of  $O_3$ -precursors reductions on  $O_3$ formation during the lockdown period. Actually, since negative CHEM contribution is inherently tied to the consumption of  $O_3$  via the  $NO<sub>x</sub>$ titration effect, the changes in IPR budget suggests that the reduction of anthropogenic  $NO<sub>x</sub>$  emissions during the COVID-19 lockdown didn't lead to a fast chemical production of  $O_3$ , but rather potentially contributed to a 42.9%, 33.5%, 32.8% and 26%  $O_3$  increase in Shanghai-JA, Hangzhou-WB, Nanjing-CM and Hefei-MS, respectively [\(Table 1](#page-7-0)). These results are supported by the work of [Wang et al. \(2022a\)](#page-12-0) that found significant decrease (increase) of chemical production (loss) of O3

#### <span id="page-7-0"></span>**Table 1**

The relative changes between the LCD and BAU scenarios of the daytime average  $(9:00-16:00 \text{ LT})$  surface  $O_3$  concentration and the corresponding atmospheric processes contributions during LD-I period between 24<sup>th</sup> Jan.-24<sup>th</sup> Feb 2020 at typical urban (Jing'an: JA; Wolong bridge: WB; Caochangmen: CM and Mingzhu square: MS) and rural sites over the YRD region (Dianshan Lake (DSL), Qiandao Lake (QDL), Dongpu Reservoir (DPR) and Shangfang Mountain (SFM)).

<sup>b</sup> Change ( $\mu$ g/m<sup>3</sup>) = LCD-BAU; Change (%) = ((LCD-BAU)/BAU) \*100.

because  $NO<sub>x</sub>$  reductions during lockdown shrunk the NO-titration effect, and hence resulting in an increase of  $O<sub>3</sub>$  concentration.

Moreover, as shown in Table 1, contrary to  $O_3$  concentration increases, the changes in CHEM-O<sub>x</sub> during LD-I were about  $-0.40 \mu g/m^3$  $(-20%)$ ,  $-0.74 \mu g/m^3$  (−22.3%),  $-0.23 \mu g/m^3$  (−11.7%) and −0.23  $\mu$ g/m<sup>3</sup> (−10.5%) in the urban sites of Shanghai-JA, Hangzhou-WB, Nanjing-CM and Hefei-MS, respectively. Similar change of CHEM-Ox of about 0.14  $\mu$ g/m<sup>3</sup> (−10.1%), −0.24  $\mu$ g/m<sup>3</sup> (−8.2%) and −0.53  $\mu$ g/m<sup>3</sup> were noted at the rural sites of DSL, QDL and SFM, respectively, except a slight increase of about 0.31  $\mu$ g/m<sup>3</sup> (14.6%) at the DPR site (Table 1).

The IPR results above highlight critical links of emission reductions (especially for  $NO_x$ ) to the increases in  $O_3$  during the lockdown period, which could be a key issue for wintertime air quality management over YRD. To have a better understanding of this challenge, we conducted comprehensive investigation of  $O<sub>3</sub>$ -pecursors sensitivities during LD-I using the CMAQ-HDDM-3D tool. We focused on probing the changes of 1st- and 2nd-order sensitivities of  $O_3$  to its precursors, and the role of emissions reductions on the dominant chemical regimes of  $O<sub>3</sub>$  formation during LD-I. This allows for a broader assessment of the extent to which  $O_3$ -precursor reductions contributed to the significant  $O_3$  increases during the lockdown period, which could eventually have positive implications to  $O_3$  control over the YRD region.

### *3.3. O3-NOx-VOCs sensitivities during COVID-19 lockdown*

[Fig. 6](#page-8-0) shows the variation of domain-wide first-order sensitivities of O<sub>3</sub> to AVOCs (anthropogenic VOCs) ( $S<sub>AVOC</sub>$ ) and NO<sub>x</sub> ( $S<sub>NO<sub>x</sub></sub>$ ), as well as the second-order derivatives to  $NO_x(S_{NO_x}^2)$  during LD-I period. Here, we quantified the  $O_3$ -precursors sensitivities that represent the daytime (9:00–16:00 LT)  $O_3$  concentration for both BAU and LCD simulations. As noted previously (and as shown in Fig.  $6$ ),  $O_3$  concentration under the LCD scenario was generally higher than that of the BAU scenario, and the increase was largest in the middle part of the YRD region. For example, the increase of  $O_3$  concentrations in Shanghai, Changzhou, Wuhu, Hefei, etc. was close to or exceeded 20  $\mu$ g/m $^3$ . Notably, almost all sensitivities had lower magnitudes under the BAU scenario ([Fig. 6](#page-8-0)a), compared to the significantly high value under the LCD scenario ([Fig. 6](#page-8-0)b). Specifically,  $S_{\text{AVOC}}^1$  barely exceeded 10  $\mu$ g/m<sup>3</sup> over the YRD domain during LD-I with a slight change of about  $2-4 \mu g/m^3$  between the BAU and LCD scenarios along the coastal cities and some areas in central YRD within Jiangsu province ([Fig. 6](#page-8-0)c). Although  $S^{1}_{\rm AVOC}$  increases were generally prevalent in the areas where  $O_3$  exhibited increased concentration, the increases of these  $(S^1_{AVOC})$  sensitivities in the central areas of YRD region consisting of highest  $O<sub>3</sub>$  increases were moderate. Meanwhile, since the second-order  $O_3$  sensitivities with respect to AVOC emissions were largely 'zero' for both scenarios, it indicated that  $O_3$ response to changes in AVOCs emissions is basically linear. Thus, it can

be concluded that reduction measures targeting key sources of AVOC emissions would yield positive effect to  $O_3$  mitigation over YRD. This is consistent with previous studies ([Wang et al., 2022a](#page-12-0); [Zhang et al., 2022](#page-12-0)).

In both the BAU and LCD scenarios,  $S_{NO<sub>x</sub>}^1$  was negative, which means that the reduction of  $NO<sub>x</sub>$  emissions would obviously lead to an increase in  $O_3$  concentration. Compared with the BAU scenario, the magnitudes of  $S_{NO_x}^1$  in the LCD scenario were significantly larger. Interestingly, compared with the BAU scenario, the areas that displayed the highest O<sub>3</sub> increases also showed significant enhancement of both  $S_{NO_x}^1$  and  $S_{NO_x}^2$ under the LCD scenario, particularly within the central areas of YRD. These areas represent the core of YRD region with high concentration of industrial activities, power plants and vehicles that emit high levels of  $NO<sub>x</sub>$ , resulting in the significant response of  $O<sub>3</sub>$  to changes in these emissions. Consequently, due to the COVID-19 lockdown the magnitudes of  $S_{NO_x}^1$  and  $S_{NO_x}^2$  were significantly enhanced, and the enhancement effect was very evident in the central areas of the YRD region where  $O_3$  increases were most prominent. Therefore, anthropogenic emission reductions during COVID-19 lockdown led to the stronger firstorder  $O_3$ -NO<sub>x</sub> sensitivities (that were largely negative and farther away from zero), as well as much stronger second-order  $O_3$  sensitivities to  $NO_x$ (that were generally positive and also farther away from zero). In short, the first- and second-order sensitivities of  $O_3$  to  $NO_x$  were intensified from the BAU scenario to the LCD scenario, presenting a convex response pattern between  $O_3$  concentrations and  $NO_x$  emission. In other words, the reduction in  $NO<sub>x</sub>$  emissions during the COVID-19 lockdown not only caused an increase in  $O_3$  concentrations, but also an increase in the absolute value of the sensitivity of  $O_3$  concentration to  $NO_x$  emission.

At the grid cells corresponding to the selected typical sites,  $O<sub>3</sub>$  under the LCD scenario displayed evidently higher sensitivities, and in both scenarios the magnitudes of  $S_{NO_x}^1$  and  $S_{NO_x}^2$  were much larger than  $S_{AVOC}^1$ ([Fig. 7](#page-9-0)a). For instance, the absolute changes of daytime average (9:00–16:00 LT)  $S<sub>AVOC</sub><sup>1</sup>$  ( $S<sub>NO<sub>x</sub></sub><sup>2</sup>$ ) st the urban JA, WB, CM and MS were 1.0 (7.7, 18.4)  $\mu$ g/m<sup>3</sup>, 2.8 (9.0, 23.4)  $\mu$ g/m<sup>3</sup>, 1.9 (11.0, 17.2)  $\mu$ g/ m<sup>3</sup> and 1.7 (7.8, 15.7)  $\mu$ g/m<sup>3</sup>, respectively [\(Fig. 7](#page-9-0)B left). Similarly, S<sub>AVOC</sub>  $(S_{NO_x}^1; S_{NO_x}^2)$  at the typical rural sites DSL, QDL, SFM and DPR changed by 2.6 (14.8, 26.9)  $\mu$ g/m<sup>3</sup>, 4.8 (17.4, 6.1)  $\mu$ g/m<sup>3</sup>, 2.9 (13.3, 34.7)  $\mu$ g/m<sup>3</sup> and 3.0 (10.6, 19.7)  $\mu$ g/m<sup>3</sup>, respectively ([Fig. 7](#page-9-0)b right). Overall, the LCD (compared to the BAU) scenario revealed that during LD-I period,  $S<sub>AVOC</sub><sup>1</sup>$ almost doubled;  $S_{NO_x}^1$  widened by about a third; and  $S_{NO_x}^2$  tripled on average at both the typical urban and rural areas of YRD. Although we noted a considerable enhancement of  $O<sub>3</sub>$ -VOC sensitivities, these results indicated that  $O_3$  was actually more sensitive to the changes in  $NO<sub>x</sub>$ emissions during the lockdown period over YRD region, which is also consistent with previous studies ([Liu et al., 2020](#page-12-0); [Wang et al., 2022a](#page-12-0)). Our findings present a rather straightforward and more elaborate understanding of the inherent changes in  $O_3$ -NO<sub>x</sub>-VOC interactions during

<span id="page-8-0"></span>

Fig. 6. Spatial distribution of simulated O<sub>3</sub> concentration and the corresponding sensitivities with respect to NO<sub>x</sub> and AVOC emissions for the (a) BAU scenario, (b) LCD scenario and (**c**) changes during LD-I period over the YRD. The values are average for the daytime hours between 9:00–16:00 local time during the lockdown period between 24<sup>th</sup> Jan.-24<sup>th</sup> Feb 2020.

the lockdown, and which provides a reasonable explanation for the observed O3 increases. Besides, our results highlight critical aspects of O3-precursor responses in the YRD region, hence forms a strong basis for assessing  $O_3$  control strategies over the region

It should be noted that non-zero magnitudes and signs of the secondorder sensitivities have been previously utilized to indicate whether a pollutant-precursor relationship is linear or nonlinear ([Wang et al.,](#page-12-0)  [2022b\)](#page-12-0). In fact, the larger the second-order sensitivity coefficients the greater the nonlinearity, and a matched (or unmatched) signs of the first- and second-order sensitivity coefficients signify a concave (or convex) nonlinear relationship ([Arter and Arunachalam, 2021](#page-12-0)). As shown in both Figs. 6 and [7,](#page-9-0)  $O_3$  response to  $NO_x$  emissions under both

simulation scenarios displayed contrasting magnitudes of  $S_{NO_x}^1$  (negative) and  $S_{NO_x}^2$  (positive), which were larger under the LCD scenario, and which could be the key reason behind the  $O<sub>3</sub>$  increases during the lockdown period. Besides, this significant variation of  $S_{NO_x}^1$  and  $S_{NO_x}^2$ during LD-I generally highlighted a convex  $O_3$ -NO<sub>x</sub> response synonymous to the widely known "NO<sub>x</sub> disbenefit" phenomenon. This is a typical characteristic feature of nonlinear chemistry of  $O_3$ -precursors formation associated with a reduced NO-titration rate, which has been applied extensively to explain the reason for the higher  $O_3$  concentrations during weekends (i.e. "weekend ozone effect") when  $NO<sub>x</sub>$  emissions are low [\(Fujita et al., 2016;](#page-12-0) [Wang et al., 2014](#page-12-0)). For detailed understanding of these changes in  $O_3$  responses to precursors we further

<span id="page-9-0"></span>

**Fig. 7.** Daytime (9:00–16:00 LT) average (**a**) O3-NOx-VOC sensitivities and (**b**) the difference between BAU and LCD scenarios during LD-I at the typical urban (left) and rural (right) locations. The LD-I is the COVID-19 lockdown period between 24<sup>th</sup> Jan.- 24<sup>th</sup> Feb 2020.

investigated the chemical regimes under which  $O<sub>3</sub>$  was formed during LD-I.

*3.4. Ozone sensitivity regimes in YRD region during COVID-19 lockdown* 

We utilized the relationship between  $S_{\text{AVOC}}^1$  and  $S_{\text{NO}_x}^1$  to describe the full range of O<sub>3</sub> sensitivity regimes during the lockdown period, we

> Fig. 8. (a) Spatial pattern  $O_3$  concentration changes (left) and sensitivity regimes for the BAU (center) and LCD (right) scenario. (**b**) Scatter plots for the 1storder O3 sensitivity coefficients with respect to AVOCs (x-axis) and  $NO<sub>x</sub>$  (y-axis) emissions for both the BAU (blue dots) and LCD (green dots) scenarios at the grid cells corresponding to typical urban JA (left), suburban DSL (center) and rural QDL (right) sites. The values are daytime average (9:00–16:00 LT) during LD-I period between  $24<sup>th</sup>$  Jan. to Feb.  $24<sup>th</sup>$ , 2020. The blue dashed lines in (B) identify the different categories of  $O_3$  sensitivity regimes: VOCsensitive, NO<sub>x</sub>-sensitive, mixed sensitivity, NOxtitration and insensitive (shaded) regimes. The definition of the different categories of sensitivity regimes are found in [\(Wang et al., 2022b\)](#page-12-0).

<span id="page-10-0"></span>utilize definitions found a previous study by [Wang et al. \(2022b\).](#page-12-0) [Fig. 8](#page-9-0)  depict the different  $O_3$  chemical regimes (i.e., VOC-sensitive, NO<sub>x</sub>-sensitive, mixed-sensitivity,  $NO<sub>x</sub>$ -titration and insensitive) over the YRD region and in selected typical sites during LD-I. Under both BAU and LCD scenarios, we generally noted that  $O_3$  formation during LD-I predominantly occurred under insensitive and  $NO<sub>x</sub>$ -titration regimes, and to a lesser extent VOC-sensitive conditions confined within specific localities ([Fig. 8](#page-9-0)a). The insensitive regime dominated most of the northern and southern areas of YRD region, which signified that  $O<sub>3</sub>$  in these areas was typically influenced either by transport and/or boundary conditions rather than photochemical formation ([Sillman and West, 2009\)](#page-12-0). The clearly defined VOC-sensitive chemistry mainly occurred around the coastal cities of Wenzhou, Zhoushan, Ningbo, Shaoxing Hangzhou Bay area, Shanghai and Nantong. We previously indicated that these coastal cities host among the largest petrochemical industries and refineries that emit VOC emissions with obvious influence on  $O_3$  formation. Furthermore, except for a few point sources in Lishui and Wenzhou we did not find locations where  $O_3$  formation was dominated by  $NO<sub>x</sub>$ - or mixed sensitivity conditions during LD-I ([Fig. 8a](#page-9-0)).

Interestingly, we also noted that major increases of simulated  $O<sub>3</sub>$ during LD-I occurred in the areas that exhibited typical  $NO<sub>x</sub>$ -titration conditions mainly in the eastern and central YRD [\(Fig. 8\)](#page-9-0). These areas usually constitute the megacity clusters and other highly urbanized areas with intense  $O_3$ -precursor emissions. Therefore, the substantial reduction of these emissions (particularly  $NO<sub>x</sub>$ ) during the lockdown period led to a sharp decrease in the chemical titration of  $O_3$  that expanded widely over larger areas, effectively exemplifying "the  $NO<sub>x</sub>$ titration trap" phenomenon [\(Tang et al., 2021\)](#page-12-0). Even at the grid cells corresponding to typical urban, suburban and rural sites of YRD,  $NO<sub>x</sub>$ -titration regime dominated the daytime  $O<sub>3</sub>$  formation with a slight increase of VOC-sensitivity under the LCD scenario ([Fig. 8](#page-9-0)b). Our findings are consistent with the studies that pointed out the prevalence of dominant NO-titration conditions during the lockdown period over the YRD region ([Wang et al., 2020a](#page-12-0), Wang et al., 2022a), but challenge other previous studies that reported the dominance of VOC-sensitive conditions [\(Liu et al., 2020;](#page-12-0) [Wang et al., 2021](#page-12-0)).

The comprehensive diagnosis of  $O<sub>3</sub>$  chemical regimes above paves

way for assessing the impact of  $O_3$  control measures. Typically, measures targeting the reduction of AVOC,  $NO<sub>x</sub>$  or both emissions are often most effective to control  $O_3$  under VOC-, NO<sub>x</sub>- or mixed-sensitivity conditions, respectively ([Wang et al., 2022b\)](#page-12-0). Otherwise, counter-productive outcomes that result in  $O<sub>3</sub>$  concentration increases could occur even with a fractional reduction of  $NO<sub>x</sub>$  (or VOC) in the VOC- (or  $NO<sub>x</sub>$ -) sensitive areas. Therefore, since the  $NO<sub>x</sub>$ -titration regime was widespread during the lockdown period, and considering the significant enhancement of  $O_3$ -NO<sub>x</sub> nonlinearity (discussed in previous section), it became necessary to assess the impact of  $NO<sub>x</sub>$  and  $AVOC$ emission reductions under the prevailing conditions. This way, we can gain further insight to ascertain the extent to which  $O_3$ -precursors reductions would influence  $O_3$  concentrations and understand why  $O_3$ spiked during the lockdown period.

## *3.5. Implications for O3 control measures*

During winter, O<sub>3</sub> hardly causes pollution according to the present National Ambient Air Quality Standards of China, but the increase of  $O_3$ concentration like those observed under the LCD scenario are usually accompanied by the change of  $O_3$  formation mechanism. We utilized the  $S_{\text{AVOC}}^1$ ,  $S_{\text{NO}_x}^1$  and  $S_{\text{NO}_x}^2$  to project the impact of a broader range of NO<sub>x</sub> and VOC reductions on O3 concentrations based on the Tylor series expansion (Eq.  $(3)$ ). As shown in Fig. 9, the impact of NO<sub>x</sub> reductions on daytime (9:00–16:00LT)  $O_3$  changes is much profound compared to AVOC reductions. At both the typical urban and rural sites,  $NO<sub>x</sub>$  reductions hinted at a significant disbenefit to  $O_3$  control over YRD. We further noted that the projections based on first-order sensitivity alone displayed lower  $O_3$  changes compared to those that included the secondorder terms (Fig. 9). For instance, at the urban JA site in Shanghai, the projections based on  $S_{NO_x}^1$  alone resulted in O<sub>3</sub> increases of about 3.9 μg/ m<sup>3</sup>, 11.6 μg/m<sup>3</sup> and 27.1 μg/m<sup>3</sup> with NO<sub>x</sub> reductions of 10%, 30% and 70%, respectively (Fig. 9 left). On the other hand, at the same site projections based on both  $S_{NO_x}^1$  and  $S_{NO_x}^2$  led to  $O_3$  increases of about 4.0 μg/m<sup>3</sup>, 13.0 μg/m<sup>3</sup> and 34.6 μg/m<sup>3</sup> (Fig. 9 right), which was about 4%, 12% and 28% higher. This clearly shows that with higher  $NO_x$ 

**Fig. 9.** Projections of daytime average (9:00–16:00 LT) ozone changes over typical (**A**) urban and (**B**) rural sites with respect to controlling a wider range of the anthropogenic emissions of either NO<sub>x</sub> (solid lines) or VOCs (dashed lines). The values are based on the simulated O<sub>3</sub> first-order (left) and both first- and second-order (right) sensitivity coefficients from both the BAU and LCD scenarios during lockdown period between 24th Jan. to 24th Feb. 2020.

reductions nonlinearity would increasingly enhance and accelerate the rate of  $O_3$  increase over the YRD region.

Therefore, in addition to the substantial weakening of the NOtitration effect it appears that the nonlinear relationship between  $O_3$ and  $NO<sub>x</sub>$  is also a critical issue that can explain the  $O<sub>3</sub>$  increases that occurred over YRD during the lockdown period. From these findings, we can recognize the usefulness of quantifying the higher- (second-) order sensitivities using the HDDM technique, so as to have a straightforward understanding of intrinsic  $O_3$ -precursors relationships that would have been otherwise overlooked by other sensitivity analysis approaches. With regards to the insignificant (mostly "zero") magnitudes of  $O_3$ second-order sensitivity to AVOC emissions, the projections presented in [Fig. 9](#page-10-0) indicate that  $O_3$  concentrations would obviously decrease linearly with respect to VOC reductions of over the YRD region. This therefore means an emission reduction strategy focusing on AVOCs emissions would yield positive benefits for wintertime  $O_3$  decrease. This is supported by other previous studies that suggested prioritization of VOC reductions to decrease  $O_3$  concentration over YRD during the winter season ([Wang et al., 2022a](#page-12-0)). Although wintertime emissions of VOCs are usually lower, especially because of the negligible biogenic VOCs and fewer evaporative sources, targeted elimination of the potential VOC emission (as opposed to  $NO_x$ ) sources especially in locations showing conspicuous VOC-sensitive chemistry would go a long way in mitigating possible O<sub>3</sub> increases during winter over the YRD region as indicated in this work.

## **4. Conclusions**

In this work, detailed investigation of the changes in  $O_3$ -precursors sensitivity and integrated process rates was conducted with CMAQbased HDDM and PA tools during the first month of COVID-19 lockdown period over the YRD region. Using simulations with (and without) developed anthropogenic emission inventory reflecting the lockdown (and "business-as-usual") conditions, we noted dramatic increase in daytime  $O_3$  (about 10-43%) that coincided with a significant weakening of the contribution (negative) of gas-phase chemistry to  $O_3$  (about 35–50%) over most areas in eastern and central YRD. Similarly, we also noted profound changes in  $O_3$ -NO<sub>x</sub>-VOC sensitivities in the same areas consisting highest  $O_3$  increases. Results showed generally negative (positive) magnitudes of first-order  $O_3$  sensitivity to  $NO_x$  (AVOC) that were mostly lower than  $-20 \mu g/m^3$  (lower than 10  $\mu g/m^3$ ) in the key cities of YRD including Shanghai, Hangzhou, Nanjing and Hefei. Most significantly, the  $O_3$  precursors emission reduction during the lockdown highlighted substantial changes of both the  $1<sup>st</sup>$ - and  $2<sup>nd</sup>$ -order O<sub>3</sub> sensitivities with respect to the changes in  $NO<sub>x</sub>$  emissions. Results show that the latter increased by about a factor of three following the emission reductions during the lockdown period. These changes in  $O_3$ -NO<sub>x</sub> sensitivities not only indicated that  $O_3$  formation during the lockdown period was largely more sensitive to  $NO_x$  than AVOCs emissions, but also the presence of a strong nonlinear and convex  $O_3$  response to changes in  $NO<sub>x</sub>$  emissions, which was indicative of a " $NO<sub>x</sub>$  reductions disbenefit" phenomenon. Besides, the concurrent manifestation of first-order sensitivities of O<sub>3</sub> to AVOC (less than 10 µg/m<sup>3</sup>) and to NO<sub>x</sub> (less than  $-10$ μg/m $^3$ ) elucidated a clearly defined NO<sub>x</sub>-titration regime that expanded considerably under the lockdown conditions.

What's more, because of the substantial changes of the  $1<sup>st</sup>$  and  $2<sup>nd</sup>$ order sensitivities of  $O_3$  to  $NO_x$  emissions, results show that at the typical urban site in Shanghai for instance, the nonlinear relationship of  $O_3$  with respect to  $47\%$  NO<sub>x</sub> reductions under the lockdown scenario potentially contributed approximately 20% increase in  $O_3$  concentration during the lockdown period. We have also shown that with higher  $NO<sub>x</sub>$  reductions this nonlinearity would progressively enhance and accelerate the rate of O3 increase over the YRD region.

Our findings generally highlighted fundamental insights regarding the significant changes of  $O_3$ -NO<sub>x</sub> sensitivities following the emission reduction measures that occurred over YRD due to COVID-19 lockdown.

In part, the results provide key insights into the underlying chemistry and nonlinear behavior of  $O_3$  under relatively high  $NO<sub>x</sub>$  reduction measures, which could be a useful hint for wintertime  $O<sub>3</sub>$  control strategy. From the simulated changes of both the  $1<sup>st</sup>$ - and  $2<sup>nd</sup>$ -order O<sub>3</sub>precursors sensitivities, our results suggest that efforts targeting VOC  $(NO<sub>x</sub>)$  reduction could be a beneficial (detrimental) strategy to reduce O3 concentrations during winter over the YRD region. We further note that with the growing improvement of emission inventories, the  $1<sup>st</sup>$ order and 2<sup>nd</sup>-order O<sub>3</sub> sensitivities to precursors in future works should elucidate and possibly isolate the sources, regions, reaction mechanisms and (if possible) the meteorological conditions that highly contribute or facilitate  $O_3$ -NO<sub>x</sub> nonlinear relationship over YRD. This would greatly enhance the current and future  $O_3$  pollution mitigation efforts in the YRD region and beyond.

Admittedly, this study still has some limitations. For example, the emissions inventory used in this study has uncertainties introduced by not considering sudden emissions. Moreover, the model performance of this study is affected by the uncertainty of the meteorological inputs generated by the WRF model, although we have validated our model against observed data. Regardless of the limitations, however, the insights and findings resulting from this study might be of interest to other city clusters in the world facing high ozone concentrations, as well as for evaluating mitigation strategies.
